Based on first-principles calculations, we showed that repeated heterostructures of zigzag graphene nanoribbons of different widths form multiple quantum well structures. Edge states of specific spin directions can be confined in these wells. The electronic and magnetic state of the ribbon can be modulated in real space. In specific geometries, the absence of reflection symmetry causes the magnetic ground state of whole heterostructure to change from antiferromagnetic to ferrimagnetic. These quantum structures of different geometries provide unique features for spintronic applications. © 2008 American Institute of Physics, [DOI: 10.1063/1.2919525]

Charge carriers of two-dimensional honeycomb crystal of graphene ribbons are expected to behave like massless Dirac fermions. Advances in materials growth and control techniques have made the synthesis of the isolated graphene1 and its ribbons2 in different orientations possible. Recent studies on the quasi one dimensional graphene ribbons revealed interesting size and geometry dependent electronic and magnetic properties.

In this letter, we showed that periodically repeated junctions of segments of zigzag ribbons with different widths can form stable superlattice structures. The energy band gap and magnetic state of the superlattice are modulated in the real space. Edge states with spin polarization can be confined in alternating quantum wells occurring in different segments of ribbons. Even more remarkable is that the antiferromagnetic (AFM) ground state can be changed to ferrimagnetic (FRM) one in asymmetric junctions.

We have performed first-principles plane wave calculations4 within density functional theory5 (DFT) using projector augmented-wave potentials.6 The exchange correlation potential has been approximated by spin polarized generalized gradient approximation7 using PW91 functional.8 All structures have been treated within supercell geometry using the periodic boundary conditions. A plane-wave basis set with kinetic energy cutoff of 500 eV has been used. In the self-consistent potential and total energy calculations, the Brillouin zone is sampled by (45 × 1 × 1) special k points for ribbons. This sampling is scaled according to the size of superlattices. All atomic positions and lattice constants are optimized by using the conjugate gradient method where total energy and atomic forces are minimized. The convergence for energy is chosen as 10−5 eV between two steps, and the maximum force allowed on each atom is 0.01 eV/Å.

Zigzag graphene ribbons (ZGNR), i.e., ZGNR(n) with n carbon atoms in its unit cell, are characterized by the states at both edges of ribbon with opposite spin polarization.9 These edge states contribute an AFM character. Under applied electric field the ribbon can become half-metallic.10 Hydrogen saturated ZGNR(n) is an AFM semiconductor and has a band gap $E_g$, which consistently decreases for $n \rightarrow \infty$, and eventually diminishes as $n \rightarrow \infty$. In the rest of the paper, all zigzag ribbons are hydrogen terminated unless stated otherwise.

Let us now consider segments of two zigzag ribbons of different widths and different lengths, namely, ZGNR(n1) and ZGNR(n2), which can make superlattice structures11 with atomically perfect and periodically repeating junctions. Normally, the superlattice geometry can be generated by periodically carving small pieces from one or both edges of the nanoribbons.2 The typical superlattices we considered and their structure parameters are schematically described in Fig. 1. ZGNR(n1)/ZGNR(n2) superlattices can be viewed as if a thin slab with periodically modulated width in the xy plane. The electronic potential in this slab is lower ($V<0$) than outside vacuum ($V= 0$). Normally, states in this thin potential slab propagate along the x axis, but the propagation of specific states in ZGNR(n2) is hindered by the potential barrier above and below the narrow segment, ZGNR(n1). Eventually, these states are confined to the wide segments, and in certain cases also to the narrow segments. Here, the confinement of the states has occurred due to the geometry of the

FIG. 1. Typical superlattice structures of ZGNR, ZGNR(n1)/ZGNR(n2). $n_1$ and $n_2$ are the number of carbon atoms in the unit cell. $l_1$ and $l_2$ are lengths of alternating ZGNR segments in numbers of hexagons along the superlattice axis. $\alpha$ is the angle between the x axis and the edge of the intermediate region joining ZGNR(n1) to ZGNR(n2). $\alpha=120^\circ$ for (a) and (b) and $90^\circ$ for (c). Dark-large balls and small-light balls indicate carbon and hydrogen atoms, respectively.

system. Defining the confinement in a segment $i$ as $\int |\Psi(r)|^2 \, dr$, the sharper the interface between ZGNR$(n_1)$ and ZGNR$(n_2)$ the stronger becomes the confinement.

In Fig. 2, we show a symmetric superlattice ZGNR(8)/ZGNR(16). Spin-up and spin-down edge states at the top of the valence band of AFM superlattice are confined to the opposite edges of the narrow segments of the superlattice. Normal flatband states near $-1.2$ eV are confined to the wide segments of ZGNR(16). The energy band structure of the superlattice is dramatically different from those of the constituent nanoribbons. If the lengths of the segments are sufficiently large, these segments display the band gap of the corresponding infinite nanoribbon in real space. The total magnetic moment of spin-up and spin-down edge states is zero in each segment, but the magnetic moment due to each edge state is different in adjacent segments. As a result, the superlattice is remained to be AFM semiconductor, but the magnitudes of the magnetic moments of the edge states are modulated along the $x$ axis. The coupling between the magnetic moments localized in the neighboring segments is calculated to be 15 meV per unit cell. The modulation of magnetic moments can be controlled by the geometry of the superlattice. For example, as shown in Fig. 2(d), the magnetic moments of the atoms in the wide segment are practically zero and hence the superlattice is composed of AFM and nonmagnetic (NM) segments. However, as $l_2 \to 10$ the magnetic moments of the edge atoms at the wide segment become significant.

The situation is even more interesting for an asymmetric superlattice, as shown in Fig. 3. While the spin-down states remain propagating at the flat edge of the superlattice, spin-up states are predominantly confined at the opposite edge of the wide segments. Confinement of states and absence of reflection symmetry breaks the symmetry between spin-up and spin-down edge states. Hence superlattice formation ends up with a FRM semiconductor having different band gaps for different spin states. In agreement with Lieb’s theorem, the net magnetic moment calculated to be $2\mu_B$ is equal to the difference of the number of atoms belonging to different sublattices. Flatbands at the edges of spin-up valence band and spin-down conduction band are of particular interest. The spin states of these bands are confined at the
discontinuous edges of the wide segment which behave as a quantum well. Since a device consisting of a finite size superlattice connected to two electrodes from both ends has high conductance for one spin direction, but low conductance for the opposite one, it operates as a spin valve. Moreover, spin-down electrons injected to this device are trapped in one of the quantum wells generated in a wide segment. As a final remark, we note that the DFT method underestimates the band gaps found in this work. However, this situation does not affect our conclusions in any essential manner.

In conclusion, through periodic modulation of the width of ZGNR in real space, one can also modulate the electronic structure and magnetic state in real space. Spins can be confined in quantum wells and the AFM ribbon can change to a PRM semiconductor. Since a finite superlattice with desired geometry can now be produced from graphene sheet by chemical methods, the modulation of electronic and magnetic states, and confined spins hold the promise for the fabrication of interesting nanodevices. For example, by applying a gate voltage through an electrode to a graphene sheet over an oxide layer, one can also generate the desired geometry. The electronic and magnetic properties of superlattices revealed in this study are important for future spintronics applications.
