Abstract

In this paper, capacitive micromachined ultrasonic transducers are fabricated using a sacrificial surface micromachining process. A testing procedure has been established in order to measure the absolute transmit and receive sensitivity spectra of the fabricated devices. The experiments are performed in oil. Pulse-echo experiments are performed and the results are compared to the pitch-catch measurements using calibrated transducers.

Keywords

cMUT, Capacitive Micromachined Ultrasonic Transducers.

I. INTRODUCTION

Capacitive micromachined ultrasonic transducers are under investigation for more than 12 years now. Many fabrication technologies are proposed in terms of a sacrificial layer processes and wafer bonding process in order to fabricate efficient ultrasonic transducers [1, 2]. The preliminary tests for the transducers are usually done in terms of the frequency spectrum of the pulse-echo signal achieved from the transducers.

In this study we demonstrate a testing procedure for cMUTs including the measurement of absolute sensitivity values of transmit and receive modes independently. A surface micromachining technology is used for fabricating the cMUTs under test. Second order effects such as membrane stress and thermal coefficient mismatch of different materials used in the process has been minimized.

The problems about the fabrication process are stressed and basic solutions are proposed for successful device fabrication.

II. FABRICATION PROCESS

A low temperature surface micromachining process is utilized for the fabrication of cMUT samples [2]. The maximum process temperature for the entire process is 250C, which occurs during the PECVD nitride deposition step. A sketch for the fabrication flow is given in Figure 1.

(a) Gold metal is used for the bottom electrode of the cMUT. Approximately 150nm of gold is evaporated on top of a thin (10-15nm) titanium layer. Titanium is used for adhesion of gold to the silicon substrate. Another option for the bottom electrode is using the silicon substrate surface as the electrode. However, this choice increases the parasitic capacitance due to the overlapping passive top electrode

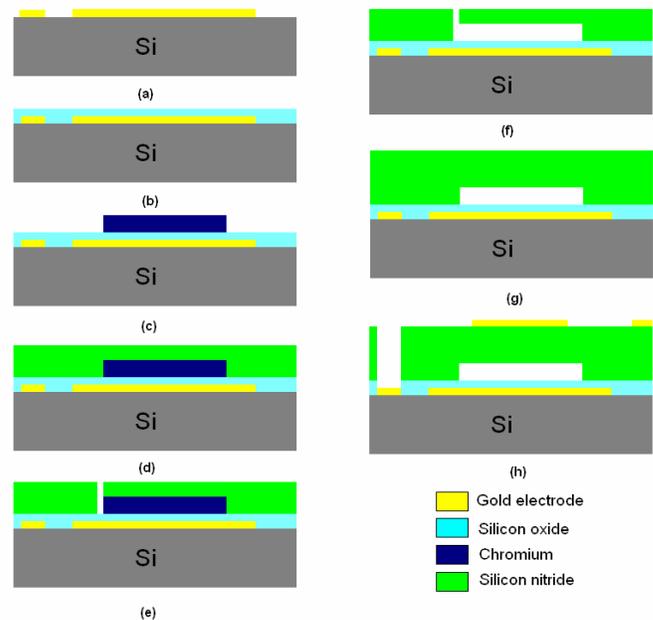

Figure 1. Microfabrication steps for producing cMUTs

areas. Furthermore, contact resistance of the silicon substrate is quite large. Ohmic contacts are needed for better contacts, which require a high temperature annealing process.

(b) We employ a thin (150nm) silicon oxide isolation layer on the bottom electrode. This layer is not an absolute necessity since the gold bottom electrode layer is resistant to the chromium etchant used during the wet release step. However we observed that a thin layer of silicon oxide or silicon nitride increases the adhesion of the gold layer. In the case of aluminum bottom electrodes, a pin-hole free isolation layer is required to protect the bottom electrode from sacrificial layer etchant.

(c) A chromium layer is sputtered as the sacrificial layer of the cMUTs [3]. Chromium is a common selection for the sacrificial layer because of its low surface roughness and high selectivity of its etchant to the silicon nitride membrane material. The thickness of this layer determines the gap height of the cMUT membrane.

(d) The membrane layer is formed in two steps. First, a one micron thick silicon nitride layer is deposited using plasma

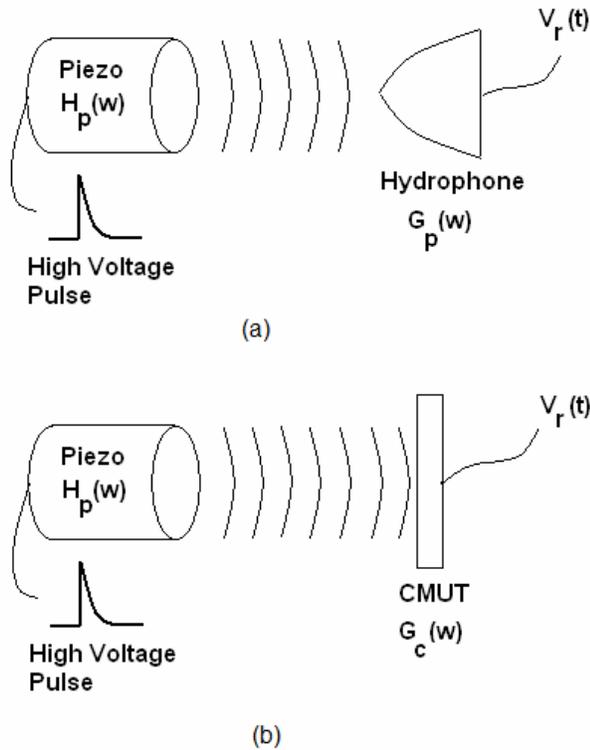

Figure 2. (a) Calibration of transmit sensitivity of piezo transducers using the hydrophone (b) Measurement of the receive sensitivity of cMUT.

enhanced chemical vapor deposition (PECVD) tool and released. The intrinsic stress of this layer is very important since this layer constitutes the suspended membrane. A high stress nitride layer would result in bowed or even cracked membranes after the release step. The process gases are mixed with helium during the deposition cycle. The amount of helium in the chamber determines the stress level of the nitride film. In this work, the nitride stress is measured to be approximately 15-20MPa tensile.

(e) The etch holes are drilled using a reactive ion etching system. Using dedicated etch holes for each membrane is critical. This way, if there is a sealing problem in any one of the etch holes; it affects only the corresponding cell.

(f) The release process takes a long time (> 6 hours.) depending on the membrane size and number of etch holes (we used at least four etch holes per membrane with 5 microns diameter, in this work).

After the release process is finished the membrane is soaked in deionized water for 2-3 hours. Then the released membranes are immersed in methanol bath for 1 hour and dried immediately. The sticktion problem of the membranes is thus minimized.

(g) A second silicon nitride layer is deposited for sealing the etch holes and bringing the membrane to its final thickness. The stoichiometry of this deposition is identical to the previous step.

(h) We used 150nm gold layer evaporated on top of a thin titanium adhesion layer, as the top electrode. Note that this process can easily be modified and the top electrode can be

sandwiched between two silicon nitride membrane layers. However this choice leads to an internal stress on the membrane due to the thermal mismatch of the electrode metal and membrane material. For the characterization purpose we placed the top electrode at the top of the membrane.

As a final step, pad openings for the bottom electrodes are drilled using the reactive ion etching system.

III. RECEIVER SENSITIVITY

The fabricated cMUTs are tested in an immersion system consisting of an oil tank, micromanipulator system and piezoelectric transducers. Oil is preferred as immersion fluid instead of water to avoid electrostatic breakdown or electrolysis. Receiver experiments are performed using three different piezoelectric transducers as transmitters and a 120 cells cMUT element as the receiver. The receiver cMUT is connected to a DC power supply for biasing the cMUT before the receive operation. An Agilent N5700 is used for the DC power supply. The transmitter piezos are driven using a JSR Ultrasonics DPR300 Pulser/Receiver.

We employed a hydrophone (Onda HGL200) and general purpose Valpey-Fisher piezoelectric transducers to calibrate cMUTs. Since the hydrophone cannot be immersed in oil, piezoelectric transducers are calibrated in water using the hydrophone first (Figure 2a) to obtain the transmitting transfer function of each piezo, $H_p(\omega)$.

The pressure field that each piezo transducer generates is measured using the calibrated hydrophone at a fixed distance at the far field range, which is 3cm in this case. If the calibrated receiver sensitivity of the hydrophone is $G_h(\omega)$ (provided by the manufacturer), the Fourier Transform of $V_r(t)$, the recorded waveform from the hydrophone using a sampling oscilloscope, Agilent DSO6052, is given as;

$$\mathfrak{F}(V_r(t)) = \mathfrak{F}(E_1 V_{in}(t)) \times H_p(\omega) \times G_h(\omega),$$

where, $\mathfrak{F}(E_1 V_{in}(t))$ is the Fourier Transform of the input waveform of transmitter. In the experiments where cMUT is a receiver, the input waveform is a wideband pulse with

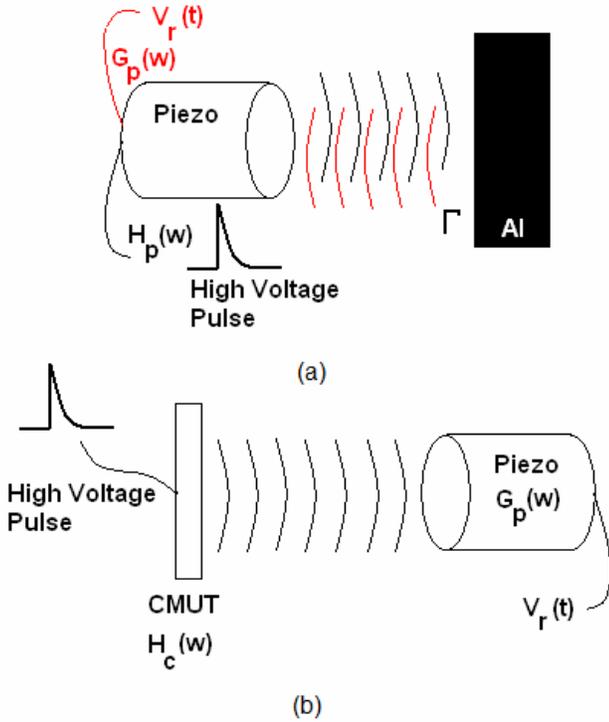

Figure 3. (a) Self calibration of the piezo transducers for receive calibration, (b) Measurement of transmit sensitivity of cMUTs.

amplitude ranging between 100V and 900V. Therefore the calibration for the transmit sensitivity of the piezo transducers can be calculated as;

$$H_p(\omega) = \frac{\Im(V_r(t))}{E_1 \times G_h(\omega)}$$

We can repeat the above procedure in oil, with hydrophone replaced by cMUT (Figure 2b), to find the receive sensitivity of the cMUT, $G_C(\omega)$. Using the transmitter sensitivity of piezo transducers, $G_C(\omega)$ can be calculated using;

$$G_C(\omega) = \frac{\Im(V_r(t))}{E_2 \times H_p(\omega)}$$

where, $V_r(t)$ is the recorded received waveform and E_2 is the pulse energy used in the experiment.

In this experiment the maximum applied DC bias to the cMUT elements is 150V. During the preliminary experiments we had problems applying DC bias voltages to the membranes larger than 200V. The top electrode gold is burnt in the case of such high voltages. This is possibly due to the electrical breakdown of silicon nitride layer. This is a serious limitation and the fabrication process must be im-

proved to increase the breakdown voltage of the membrane material.

The open circuit receive sensitivity can be obtained only if an accurate knowledge of cMUT input impedance in immersion is available. The measured sensitivity can then be corrected for open circuit sensitivity, which can be significantly larger. The output impedance of the transmitter circuitry is 50Ω whereas the input impedance of the receiver amplifier is 500Ω . The results reported in this work are uncorrected measured sensitivity with respect to these terminations.

The receive sensitivity of cMUT in dB re $1V/\mu Pa$ is given with respect to frequency in Figure 3 for a cMUT element for different bias voltages.

IV. TRANSMITTER SENSITIVITY

A similar measurement setup is used in order to determine the transmitter sensitivity of cMUTs. We calibrated piezoelectric transducers for reception, we cannot use the hydrophone directly in oil. Since we already know the transmit sensitivity of the piezoelectric transducers from the previous experiments, we employed pulse-echo measurements to calibrate each transducer. The transmitted acoustic pulse is reflected from an aluminum block and received by the same transducer (Figure 4a). The total flight time is maintained at 3 cm, again. Transmit/Receive mode of DPR300 is used and the received waveform is recorded using a sampling oscilloscope. Using the transfer functions of the transducers, the received signal can be expressed as;

$$\Im(V_r(t)) = \Im(E_1 V_{in}(t)) \times H_p(\omega) \times G_p(\omega) \times \Gamma,$$

where, $G_p(\omega)$ is the receive sensitivity of the piezo and Γ is the reflection coefficient of the aluminum plate (0.85). Therefore the receive sensitivity of the piezo transducers can be written as;

$$G_p(\omega) = \frac{\mathfrak{I}(V_r(t))}{E_1 \times H_p(\omega) \times \Gamma}$$

If the aluminum block is replaced by the cMUT under test and the distance between the receiver and the transmitter is adjusted to 3cm (Figure 4b), the transmitter sensitivity of the cMUT, $H_C(\omega)$, can be found using the recorded waveform as;

$$H_C(\omega) = \frac{\mathfrak{I}(V_r(t))}{E_2 \times G_p(\omega)}$$

where, E_2 is the pulse energy of the input electrical pulse to the cMUT. Note that in this case only 100V and 150V pulses are applied to the cMUTs in order to prevent the electrical breakdown. In Figure 5 transmit mode sensitivity of a cMUT is depicted with a 100V pulse applied to cMUTs for different biases.

It can be seen in the figures that we have observed some notches at the frequency spectrum of receive and transmit sensitivities of the cMUT. Those notches occur possibly because of the substrate ringing of the cMUTs. During the experiments the cMUT die is glued to a PCB and attached to a thin aluminum holder.

The transmit sensitivity can be obtained only if an accurate knowledge of cMUT input impedance in immersion is available. The measured sensitivity can then be corrected for matched transmit sensitivity. Our calculations show a closer match to a short circuit transmission sensitivity since input impedance of the cMUT is much larger than 50Ω.

V. PULSE-ECHO MEASUREMENTS

Different from the previous measurement setups, we performed pulse-echo experiments using only the cMUT as both the receiver and the transmitter. The transmitted pressure pulse is reflected from an aluminum block with a reflection coefficient of Γ . Note that the block is placed at 1.5cm away from the cMUT transducer in order to achieve the same conditions as the previous experiments. The transmit/receive sensitivity which is the insertion loss of the cMUT is calculated using the measured waveform;

$$H_C(\omega) \times G_C(\omega) = \frac{\mathfrak{I}(V_r(t))}{\mathfrak{I}(E_1 V_{in}(t)) \times \Gamma}$$

The applied pulse amplitudes to the cMUTs in the transmit cycle was 100V on top of a 25 & 50V of DC bias. During the receive cycle only 50V DC bias is applied to the cMUT transducers. It is depicted in Figure 6 that, pulse echo experiments show an agreement with the calculated curves using the pitch-catch experiment results.

VI. CONCLUSIONS

The fabrication and characterization of cMUTs are reported in this paper. The problems that are encountered in the fabrication process are discussed. cMUTs are immersed in oil for characterization. A measurement setup and procedure is developed and receive and transmit sensitivity of cMUTs are determined in terms of absolute values. Calculated sensitivity values are used to compute the pulse-echo response of the cMUTs. Computed spectrum shows a good agreement with the measured pulse-echo response of the cMUT
