(Received 12 December 2011; accepted 8 March 2012; published online 9 April 2012)

Taking advantage of the favorable Gibbs free energies, atomic layer deposited (ALD) aluminum oxide (Al$_2$O$_3$) was used as a novel approach for passivation of type II InAs/GaSb superlattice (SL) midwave infrared (MWIR) single pixel photodetectors in a self cleaning process ($\lambda_{\text{cut-off}} \approx 5.1 \mu$m). Al$_2$O$_3$ passivated and unpassivated diodes were compared for their electrical and optical performances. For passivated diodes, the dark current density was improved by an order of magnitude at 77 K. The zero bias responsivity and detectivity was 1.33 A/W and 1.9 $\times$ 10$^{13}$ Jones, respectively at 4 $\mu$m and 77 K. Quantum efficiency (QE) was determined as %41 for these detectors. This conformal passivation technique is promising for focal plane array (FPA) applications.

I. INTRODUCTION

A critical step in the fabrication of optoelectronic devices is the passivation of the exposed surfaces. Such surfaces are often created in order to confine current or light. In photodetectors, the requirement for the confinement of current is met by fabrication of a mesa structure, which results in a large number of surface states generated due to the abrupt termination of the crystal structure on the mesa side walls. Ensuing surface leakage currents are typically due to dangling bonds, inversion layers, and interfacial traps leading to lower responsivity. In photodetectors based on III-V materials, etched surfaces exposed to atmosphere form thin layers of native oxides some of which are good conductors, increasing the shunt current. Photodetectors with small pixel sizes (<25 $\mu$m) suffer from surface leakage more than large pixel photodetectors due to their higher perimeter to area ratio. Thus, for focal plane array (FPA) applications and long wavelengths, passivation becomes an especially vital issue. In order to overcome surface leakage currents, various passivation methods such as ammonium sulfide passivation, deposition of silicon dioxide layer, polyimide layer, and overgrowth with wide bandgap material have been used. Passivation is expected to suppress oxidation of the side walls and saturate dangling bonds to prevent surface states. Sulfur passivation replaces oxygen with sulfur at the mesa walls and saturates dangling bonds to prevent surface states.

gas phase reactions on the surface of the SL photodetector. The growth of Al₂O₃ with ALD uses two gases that are introduced to the chamber one at a time and which react with the gas on the surface adsorbed during the previous sequence. ALD deposited Al₂O₃ has many advantages as a passivation layer such as the control of thickness at the molecular level since in the ALD process, thickness depends on the number of reaction cycles. This leads to a precise thickness control as well as perfect conformal coverage even at sharp edges, large area thickness uniformity, very low process temperatures, and plasma free operation. Furthermore Al₂O₃ is a very good dielectric over a very large frequency range. In the case of T2SL photodetectors where mesa etching leads to uneven etching of very thin InAs and GaSb layers at the side walls, conformal coverage at the atomic level may be very beneficial. These properties of ALD grown Al₂O₃ make it a perfect candidate for passivation of InAs/GaSb super lattice FPA photodetectors. No use of Al₂O₃ as a passivation layer has been made so far for InAs/GaSb super lattice system.

II. EXPERIMENTAL

The sample studied in this work was grown commercially (IQE Inc. USA) with molecular beam epitaxy on a GaSb substrate. The photodetector is designed as p-i-n photodetector with design cutoff wavelength of 5 μm. It starts with 100 nm thick GaSb buffer layer and 20 nm AlₓGaₓAsᵧSb as an insulator and etch stop layer, followed by 1000 nm GaSb:Be (p = 1.0 × 10¹⁷ cm⁻³) p contact layer. P-i-n part of the design consist of 90 periods 8 monolayers (MLs) of InAs/8 MLs of GaSb:Be (p = 1.5 × 10¹⁷ cm⁻³) p-type layers, 60 periods 8 MLs of InAs/8 MLs of GaSb i-layers, 60 periods 8 MLs of InAs:Te (n: 5 × 10¹⁵ cm⁻³) n-type layers and structure is terminated by 20 nm InAs:Te (n: 5 × 10¹⁵ cm⁻³) cap layer to assure good ohmic contact. Appropriate shutter sequences were applied to compensate the tensile strain caused by lattice mismatch between InAs and GaSb layers. Single pixel photodetectors were fabricated with 400 × 400 μm mesa size. To minimize surface damage, mesas have been fabricated by standard lithography and wet etch solution. Mesa-isolated photodiodes are defined at room temperature, using the chemical solution based on H₃PO₄/C₆H₅OH/H₂O/CH₃OH/H₂O with 200 nm per minute etch rate. The etch process has been stopped when etch depth reached the bottom contact layer. The etch depth was about 1.5 μm. 200 cycles Al₂O₃ passivation layer deposition carried out in atomic layer deposition system (Cambridge Nanotech Savannah 100) with 150 °C as the substrate holder temperature. Growth of Al₂O₃ has been done by delivering 0.015 s water vapor (H₂O) and 0.015 s trimethylaluminum (TMA) pulses into the chamber in a sequential manner under constant 20 sccm N₂ gas flow. A wait time of 20 s was added after each pulse to ensure surface reactions to take place. Both trimethylaluminum and water were unheated. The thickness of the film grown in this manner was determined as 20 nm by subsequent etching and measurement of the Al₂O₃ film. Ohmic contacts were made by evaporating 5 nm Titanium (Ti) and 200 nm Gold (Au) on the bottom and top contact layers of the detectors. Fabricated detectors were bonded to a chip carrier for further characterization. Exact same procedures were applied to another sample without Al₂O₃ passivation to act as a reference detector.

III. RESULTS AND DISCUSSION

To investigate the effect of Al₂O₃ passivation, samples were mounted on a liquid nitrogen cooled cold finger. Dark current measurements were performed at 77 K by using a HP41420A source-measure unit. Figure 1 shows the measured dark current density versus applied bias voltage characteristics of the unpassivated and Al₂O₃ passivated 400 × 400 μm single pixel test diodes at 77 K. Single pixel passivated detector shows at least an order of magnitude reduction on dark current density compared with an unpassivated detector. At -0.1 V bias voltage, dark current density reduced from 4.7 × 10⁻⁷ A/cm² to 6.6 × 10⁻⁸ A/cm². These measurements yielded R₉Ω product values of 1.6 × 10³ Ω cm² and 3.7 × 10⁵ Ω cm² for the unpassivated and Al₂O₃ passivated samples, respectively. At -0.1 V bias and 77 K, Al₂O₃ passivation shows improved dark current results when compared with SiO₂ and SU8 passivation.⁶,¹⁶ The prominent reduction in dark current due to ALD deposited Al₂O₃ passivation is very encouraging for use in FPA applications.⁶,¹⁷ Spectral response of the photodetectors was measured using a Fourier transform infrared spectroscopy (Bruker Equinox 55) and a liquid nitrogen cooled cold finger system. Figure 2 shows spectral response of the unpassivated and Al₂O₃ passivated photodetectors measured under single pass and front side illumination condition. The cut-off wavelength of the Al₂O₃ passivated and unpassivated photodetectors is determined to be 5.1 μm.

FIG. 1. (a) Dark current density vs applied bias of unpassivated and Al₂O₃ passivated 400 μm single pixel square diodes measured at 77 K. (b) Zero bias differential resistance vs applied bias voltage characteristics for the unpassivated and Al₂O₃ passivated samples at 77 K. Dashed line represents Al₂O₃ passivated device and solid line represents unpassivated device.
The responsivity of the photodetectors has been measured at 77 K using calibrated blackbody source at 800°C (Newport, Oriel 67 000), lock-in amplifier (SRS, SR830 DSP) and mechanical chopper (SRS, SR540) system. Photodetectors were illuminated with a 300 K background with a 2\pi field-of-view. A 3-5 \mu m blackbody filter has been use to eliminate unwanted illumination. Figure 3 shows responsivity and calculated Johnson-noise limited detectivity (D*) versus applied bias voltage graph for Al2O3 passivated photodetector. The zero bias responsivity of Al2O3 passivated photodetector was equal to 1.33 A/W at 4 \mu m and 77 K. Under zero bias, the peak D*, was equal to 1.9 \times 10^{13} Jones for the Al2O3 passivated single pixel photodetector at 4 \mu m and 77 K. Quantum efficiency (QE) of the passivated photodetector has been determined as % 41 for single pass front illumination condition. When we compare our results with recent publications,\textsuperscript{6,16–19} ALD grown Al2O3 passivated T2SL photodetectors are very promising. In FPA applications, larger perimeter to area ratio increases the effect of surface leakage in the operation of the smaller FPA detectors and passivation becomes an important issue. ALD grown Al2O3 passivation technique may be a good candidate also for LWIR photodetectors. This will be especially true for photodetectors designed to operate in the LWIR region due to relatively small bandgap of the LWIR photodetectors, where surface leakage currents are more dominant. Work is in progress to demonstrate this.

To understand the nature of the dark current, temperature dependent measurements of the dark current has been done. Relationship between the dark current densities and inverse temperatures at −0.1 V bias are shown in Fig. 4. The I-V curve is dominated by diffusion current at high temperatures and generation-recombination current at low temperatures. The diodes with Al2O3 passivation show lower dark current than unpassivated photodetectors at low temperatures. This indicates that the Al2O3 passivation satisfies surface states and prevents current flow through the surface channel. Al2O3 passivated photodetectors show Arrhenius type behavior above 100 K, characterizing the dominant bulk diffusion current. The activation energy has been calculated as 0.233 eV, which is close to the device bandgap. For lower temperatures the current begins to divert from the Arrhenius type of behavior. Generation recombination (G-R) current becomes dominant for mid temperatures. At 40 K dark current density shows a tendency to decrease indicating that surface leakage starts to become important in this temperature range.\textsuperscript{20} For the unpassivated detector, dark current density deviates from the Arrhenius type of behavior at temperatures lower than 120 K indicating surface related currents are dominant at this range.

The influence of Al2O3 on the performance of the T2SL is closely related to the interface chemistry of the Al2O3/SL. Components of InAs/GaSb SL are chemically very reactive. Their surfaces are easily oxidized and a native oxide layer of several nanometers thick is quickly formed upon exposure to air.\textsuperscript{21} Oxygen diffuses through the surface, reacts with both
Ga and Sb, and forms oxide layers, through the chemical reaction $2\text{GaSb} + 3\text{O}_2 \rightarrow \text{Ga}_2\text{O}_3 + \text{Sb}_2\text{O}_3$.\(^{15}\) Using the same argument leads to oxidation of In and As such that $2\text{InAs} + 3\text{O}_2 \rightarrow \text{In}_2\text{O}_3 + \text{As}_2\text{O}_3$.\(^{22}\) Further, In$_2$O$_3$ and As$_2$O$_3$ may react and form InAsO$_3$ (Ref. 23) since In$_2$O$_3 + \text{As}_2\text{O}_3 \rightarrow 2\text{InAsO}_3$. This mechanism is responsible for the formation of additional conductive channels and, consequently, leads to a large surface component of dark current. Reduction of the oxides during the ALD deposition is due to favorable Gibbs free energies for forming Al$_2$O$_3$ compared to As, Ga, Sb, and In oxides. Al$_2$O$_3$ formation is energetically preferred to native oxide of InAs and GaSb.

Alternatively, Al$^{+3}$ atoms in the trimethylaluminum (TMA) molecule could possibly replace As atoms that form As$_2$O$_3$ or In atoms in an In$_2$O$_3$ molecule.\(^{24}\) Similar reaction pathways with oxides of other metal atoms are also possible. These are so called interfacial self cleaning reactions of surface oxides.\(^{7}\) Reduction of oxides after Al$_2$O$_3$ deposition for GaSb and InAs has been confirmed by XPS measurements.\(^{11,12,25}\)

Finally, in the case of T2SLs with large numbers of very thin dissimilar layers, different etch rates of InAs and GaSb lead to roughness on the mesa side walls. Conformal coating of atomic layer deposition creates a perfect protective layer against environmental effects especially against oxidation. This conformal coverage of rough surfaces also satisfies dangling bonds more efficiently while eliminating metal oxides in a self cleaning process. This makes ALD Al$_2$O$_3$ a perfect candidate for passivation of InAs/GaSb superlattice photodetectors. That this state-of-art passivation technique results in high responsivity and detectivity and very low dark current is a clear indication of improvements due to self healing ALD Al$_2$O$_3$ passivation process.

IV. CONCLUSION

In conclusion, we have demonstrated the suppression of dark current and increase in optical response of the InAs/GaSb superlattice photodetectors with cutoff wavelength at 5.1 µm (MWIR). We have used ALD deposited Al$_2$O$_3$ passivation layer on InAs/GaSb p-i-n design superlattice photodetectors. Plasma free and low operation temperature with uniform coating gave us conformal and defect free coverage on the side walls. Al$_2$O$_3$ passivated superlattice photodetectors reduced the dark current from $4.7 \times 10^{-5}$ A/cm$^2$ to 6.6 $\times 10^{-7}$ A/cm$^2$ compared to unpassivated photodetector at 77 K and under $-0.1 \text{V}$ applied bias condition. Corresponding zero bias area product ($R_0$A) improved at least an order of magnitude (from $1.6 \times 10^3$ Ω·cm$^2$ to $3.7 \times 10^5$ Ω·cm$^2$). The zero bias responsivity and detectivity (D*) are determined as 1.33 A/W and 1.9 $\times 10^{13}$ Jones, respectively for the Al$_2$O$_3$ passivated photodetector at 4 μm and 77 K. Quantum efficiency (QE) of the passivated photodetector has been determined as % 41 for single pass front illumination condition. Temperature dependent dark current measurements revealed that passivated devices show Arrhenius type of behavior at higher temperatures which is indication that dominant current is bulk diffusion current. The calculated activation energy is equal to 0.233 eV, which is close to the device bandgap. This work shows that ALD coated Al$_2$O$_3$ is a good material as a passivation layer for p-i-n design InAs/GaSb superlattice photodetectors.
